ABSTRACT

Vermifiltration is a new technology using earthworms to process organically polluted water. A pilot associated with a swine facility (piggery) with 66 swine was developed to treat diluted manure, produce earthworms and vermicompost, and reduce air pollution. The aim of the experiment reported here was to devise an integrated method - biological, chemical and physical - for further research and development of vermicomposting in dilute swine manure, and provide some preliminary results. The earthworm population increased by 30% in 4 weeks, indicating the acclimation of the earthworms. A reduction in ammonia emission was observed of about 50% for the whole system. Higher water (+100%), carbon (+70%), and total nitrogen (+80%) gaseous losses were observed compared to conventional breeding on a slatted floor. This methodology can be used for further studies to develop vermicomposting for earthworm and vermicompost production from diluted animal manure, without pollution transfer.

1. Introduction

Animal farms use huge amounts of water and produce effluents that are generally spread on soils in Europe or directly released into rivers in some countries. Recycling of water is an essential factor in their economic and environmental improvement. Vermifiltration (or lumbrifiltration) is a new technology to process organically polluted water using earthworms. It was first advocated by the late Prof. Jose Toha at the University of Chile in 1992 (Aguilera, 2003; Bouché and Qiu, 1998). Worms and vermicompost can be sold to compensate for the cost of water treatment and reduce the amounts of manure spread on farm fields.

The benefits of earthworms in recycling liquid or solid organic residues have already been highlighted (for instance: White, 1996; Hertle et al., 2002; Sinha et al., 2002; Bajsa et al., 2003; Taylor et al., 2003; Bouché and Soto, 2004; Hughes et al., 2007). Vermicompost is the final product of organic wastes processed by earthworms. It improves the physical, chemical, and microbial properties of container media or...
soil, and stimulates plant growth (Katie et al., 1992; Sinha, 1997; Riggle, 1998; Szczepan, 1999). Eastman et al. (2001) and Eastman (1996) observed that vermicompost could greatly reduce human pathogens in domestic wastewater sludge. Similar benefits may be expected when wastewater is filtered through a medium containing large numbers of earthworms. Earthworms were also regarded as bioindicators in ecotoxicity studies (Ferrière et al., 1981; Callahan, 1988; Bouche and Qiu, 1993).

Previous studies on vermifiltration only investigated the treatment's efficacy on water quality. However, information on the population dynamics is also important to maximize the treatment capacity of the system. Moreover, the development of a new technology in agriculture should not increase the environmental impact. The control of gaseous emissions is therefore also important, since livestock production is a significant source of ammonia and greenhouse gases on the global scale.

However, few, if any, studies of vermifiltration have been made with animal manure. In most regions with intensive livestock production, excessive releases of liquid and solid manure lead to water, soil, and air pollution. Therefore, a vermifiltration project was set up to process the wastewater from a swine facility (piggery), recycle the treated water to remove the manure by flushing, and improve the management of biosolids. Empirical development led to a design allowing continuous operation throughout the year.

The aim of the work reported in this paper is to describe an integrated method to study this vermifiltration system on two time scales: short-term changes for management purposes (earthworm population, gas emission), and long-term changes for environmental evaluation (mass balance of C, N, H₂O).

2. Materials and methods

2.1. Experimental design and operation

Vermifilter design and management were developed empirically for 2 years before this experiment, using redox potential monitoring to avoid sprinkling with highly reduced water. All the details given below were found to be important for the continuous growth and reproduction of the earthworms throughout the year. The basic medium was a mixture of wood chips (one-third of total mass) and earthworm (Eisenia fetida) litter (two-thirds of total mass), the latter being the part containing most of the earthworms in the four vermifilters before this experiment. The wood chips and the litter contained 46 and 26% dry matter, 16 and 9.6% total carbon, 0.09 and 0.44% total nitrogen, 0 and 0.05% ammoniacal nitrogen, 0.01 and 0.19% total phosphorus, 0.05 and 0.14% total potassium, respectively. The litter was made of bark, wood chips, peat, straw, and vermicompost resulting from previous experiments to compare various materials and mixtures, and to calibrate the sprinkling schedule. Initial composition of the vermifilter is given in Table 1. The material was about 0.17 m high. It was supported by a slatted floor and a non-woven synthetic fabric (Fig. 1). Its surface was arranged into furrows and ridges so that the worms could inhabit the ridges when the water could not drain rapidly during sprinkling. Four vermifilters 5 m long × 2.5 m wide × 1 m high were placed in a room with natural ventilation.

The swine facility housed 66 growing-finishing swine with standard diet. It was mechanically ventilated and equipped with a flushing system under the slatted floor (Mainet et al., 2007). It was flushed every 4 h using about 650 l from tank 4 (Fig. 1). Flushing removed the swine excreta. The diluted manure (wastewater + flushing liquid + excreta) was collected in tank 1. In this paper, 'excreta' means all outputs from swine metabolism and gut transit (e.g. urine or feces), while 'excretion' (or 'theoretical excretion' in Table 1) refers to ingestion minus swine growth and respiration (i.e. defecation, gas exhalation, and excretion sensu stricto).

Then, the diluted manure was put through a sieve to retain the coarsest suspended solids. After sieving, all the fresh liquid manure in tank 2 was sprinkled onto a vermifilter on 2 days per week to treat the wastewater and to feed the earthworms. The instantaneous and weekly sprinkling density were equivalent to 0.75 and 2.6 m² vermifilter/swine, respectively. In order to avoid water accumulation, the amount sprinkled was limited to 51 m⁻² per 10 min period. The amount sprinkled per vermifilter could not be adjusted exactly to the same value for all four vermifilters: it was about 20% higher for v1 and v2 than for v3 and v4. Maximum percolation rate

* Gaseous emissions of dry matter are not estimated.
* Loss = (final - start) * % dry matter - final - tank after vermiliter/accumulation; we assume that the losses of C and N from the tank after slurry can be ignored (less than 10% of input).
* Inputs of carbon, nitrogen, phosphorus, and potassium in the top water are ignored.
* All of which represent 10% was ammonia and 90% was ammonium nitrate.
* Gaseous emissions of phosphorus and potassium are ignored.
* Accumulation = final - tank after-vermiliter - initial/accumulation.
was 0.41 min⁻¹ m⁻². The treated water was collected in tank 4 (Fig. 2) and then pumped to flush the swine facility so that the water was recycled. It was necessary to add tap water to tank 4 to have enough water for the flushing.

On the 5 days per week when the vermi filter was not sprinkled, the swine facility was flushed with the sieved effluent from tank 2. Tap water was added to tank 2 at the beginning of the 5 days period. This formed a cycle, bypassing the vermi filter. When tank 2 was full, the excess liquid flowed into a neighboring pit (tank 3). Before beginning the next 2 days’ sprinkling of the vermi filter, tank 2 was emptied into tank 3 so that no old slurry could reach the vermi filter.

During the experiment, all the solids and liquids entering the system were stored. The food and water added in the swine soup (pigswill) were recorded by the food mixing system. All the tap water added manually in the tanks was recorded with a volumetric counter. The swine and the sieved solids were weighed each week.

The whole process was controlled automatically by a computer, and lasted 5 weeks.

2.2. Solid and liquid sampling and analysis

When filling the chambers with new materials and removing vermi filter material to the outside at the end of the experiment, wood pieces and litter with earthworms were randomly sampled. For each vermi filter, over 50 subsamples were taken to make one sample of ca 50 kg. These four vermi filter samples, gently mixed, were divided into small units for chemical analysis and dry matter measurements.

In addition, between the filling and emptying dates, vermi filters were sampled 1, 2 and 4 weeks after filling the four chambers. Each sampling was done at least 1 day after the end of sprinkling, using a stainless steel pipe sampler with a sharpened edge, allowing it to be pushed into the vermi filter materials manually. Its length was 1 m and its internal diameter 0.11 m, to limit damage to earthworms. We sampled 3 equidistant points in each ridge and each of the 4 inside furrows, totaling 27 samples per chamber, weighing around 40 kg. The sample depth was about 0.4 m. All the 27 samples were gently mixed and subdivided until small samples were obtained. This mixture was sampled again to fill six small plastic boxes and two bags, totaling about 6 kg. The remaining material was returned to the original chamber.

The material from one bag was chopped and used for chemical analysis, the other being stored in a deep freeze at -18 °C. Three small plastic boxes of samples were weighed and oven dried at 105 °C to measure the dry matter content. The other three boxes were weighed and used to count the earthworms (adults, sub-adults, juveniles and cocoons). All the worms taken out of each box were kept on moist paper towels at room temperature in the dark for 2 days to empty their gut content by defecation. Then the worms and cocoons were dried at 105 °C to measure their dry biomass.

The initial volume was not measured because negligible volume decrease during the experiment was initially expected. After the first week, before sampling, the volume of the vermi filter was estimated by measuring the level of each furrow and ridge at 3 places, totaling 45 points.

The liquids in the system were sampled at the beginning and end of the second sprinkling period to estimate the partitioning of the elements throughout the system: treated water before flushing (tank 4), diluted swine manure (tank 1), sieved effluent before flushing (tank 2), and treated water just out of vermi filter before tank 4. On these liquids, dry matter content was measured and chemical analysis was carried out. After 5 weeks, the volume of treated water was measured in tank 4 and the slurry in tank 3 was weighed. Both liquids were carefully sampled and stored in the deep freeze at -18 °C before analyzing.

The solid and liquid samples were analyzed for total nitrogen (TN, Kjeldahl method, NF EN 25 663), total phosphorus (TP, colorimetric assay after acid extraction of the ash, NF V18-106), total carbon (TC, CO₂ emission after acid treatment of the
wet sample, NF ISO 10 693), total organic carbon (TOC, Anne method by chemical oxidation and spectrometry, NF ISO 14 235), total potassium (TK, atomic absorption after extraction of the ash, NF V18-106), ammoniacal nitrogen (NH₄-N, distillation after MgO addition to the wet sample). The composition of the swine food, as indicated by the manufacturer, is given in Table 1.

2.3. Air measurements

NH₃ and CO₂ were measured in the swine facility, vermicompost, and outside air, using colorimetric tubes (Draeger™). Temperature and humidity were measured manually with a thermohygrometer (Testo). Nine days' measurements were used to characterize the 5-week experiment. N₂O was measured continuously in the swine facility and the vermicompost atmospheres with a photoacoustic spectrometer (Innova, 3426) during the last 3 weeks. The minimum concentration observed (0.33 ppm N₂O) was taken as the outside concentration to calculate the concentration gradient.

2.4. Data processing

Swine excrement was calculated as the difference between the food input and the gaseous outputs and swine live weight (Dourmad et al., 2002; CORPEN, 2003). The gaseous outputs were assumed to be only CO₂ and water vapor. CO₂ production was deducted from the total heat production, with a simple equation using the swine live weight (CIGR, 1984). Water vapor produced by the swine respiration was deducted from the total heat production and a latent heat ratio of 45%. The metabolic water production was calculated from heat production, assuming 1 mol of water produced for 1 mol of CO₂.

The emission from the swine facility was calculated from concentration gradients and ventilation estimates (Phillips et al., 1998). The concentration gradient was deduced from the concentration measurements described above and the air density calculated from temperature and humidity measurements. The ventilation was calculated from the total heat produced by the swine and the enthalpy difference between inside and outside air. The sensible heat lost through the walls was calculated using 0.9 W K⁻¹ per swine as insulation coefficient of the building.

The emissions of CO₂, NH₃, and N₂O from the vermicompost were calculated assuming that all of the water deficit was due to evaporation by the vermicompost. In fact, water deficit corresponds to the difference between inputs (initial water + water additions), and outputs (final water in tanks + water in the swine and solid effluents + water vapor output of the swine facility). Then the ratios of the mean concentration gradients (inside – outside) of CO₂, NH₃, or N₂O to water were used to estimate the gas emissions. The concentration increase during the spraying periods was negligible when compared to the air humidity increase, so these periods were neglected.

All the values of chemical analysis and gas emission were used to calculate the deficit of the mass balance in the whole system and to evaluate the treatment efficiency of the vermicompost system. Microsoft Excel 2000 was used to carry out statistical analyses and to draw figures. The results were expressed as mean±standard error and were analyzed by Student’s t-test at a significance level of P < 0.05.

3. Results and discussion

3.1. Temperature and humidity in the vermicompost

The measured relative humidity in the sampled materials was 60–80%, considered ideal for earthworms. The air temperature varied between 16 and 30 °C above the vermicompost, between 23 and 30 °C inside the swine facility, and between 13 and 30 °C outside. We noticed that the vermicompost was warmer than the sprinkled water, suggesting that active composting occurred inside it. The rather high porosity of the material also allowed diffusion of gases, especially ingress of oxygen and release of carbon dioxide. The exothermic biotransformation inside the vermicomposts induced a temperature increase, while sprinkling ensured moist conditions throughout the period and helped to prevent over-heating.
3.2. Increase in earthworm population and biomass

There was no accumulation of mud in the vermicompost material during the experiment, but dense small holes and numerous earthworm casts on the surface indicated intense earthworm activity. During sprinkling, earthworms can die within a few hours if either too much water or too much organic matter or anoxic liquid is added to the vermicompost. This was not observed. It shows that both the water and the organic matter inputs were neither excessive nor toxic during sprinkling, since earthworms have been used in standard tests of ecotoxicity (Bernier et al., 1991; Callahan, 1988; Boutch et al., 1998). Between the sprinkling periods, the living conditions were also suitable as indicated by the growth of the population and the biomass, and the numbers of cocoons and juveniles (Figs. 3 and 4).

Most of the studies on vermicompost or vermiculture have investigated the chemical changes in the substrate and the growth of individual earthworms under laboratory conditions, and a few of them have recorded the dynamics of the earthworm population (Gunadi et al., 2003; Garg et al., 2005). On a pilot scale, working densities for particular vermicomposting systems have been reported to be between 1 and 4 kg earthworms (wet weight) per m² of bed (Frederickson and Ross-Smith, 2003).

The maximum number of earthworms at the end of our experiment was 11–20 × 10⁶ worms m⁻², i.e. similar to the density in commercial breeding sites (Agullera, 2003). The differences between two consecutive values were not always significant, but all the initial values were significantly different from the values at 4 weeks in the same vermicompost. The observed increase in earthworm population indicated that living conditions were suitable, and enough nutrients were supplied to the vermicompost.

The maximum wet weight at the end of the experiment was between 1 and 1.5 kg m⁻², and the corresponding dry weight was between 140 and 197 g m⁻². This showed indirectly that the earthworms did not escape from the sampling area to the sides or bottom of the vermicompost. The increase in biomass ranged from 79% in v3 to 22% in v2 after 4 weeks and the average value for the 4 vermicomposts was 130%. This increase of 1.3-fold within 1 month was in the same range as in previous studies (Frederickson and Ross-Smith, 2003).

The biomass and abundance increases were higher in vermicompost v1 and v2 than in v3 and v4. This could be related to the control of the amount of sprinkled slurry, which was about 20% higher for v1 and v2. It indicated that more liquid manure could be applied. These increases not only strengthen the capacity of vermicompost to treat the organic pollutant in the effluent and to produce earthworms and vermicompost, but also are an integrated biological indicator of earthworm conditions. Therefore the system design, the effluent quality, the sprinkling program, the earthworm abundance, and the vermicompost material in this study were adequate.

3.3. Cocoon and juvenile production

The main group contributing to the population increase was the juveniles. Significant differences between juvenile abundance at 1, 2, and 4 weeks (Fig. 4) did not induce similar differences in adult populations because it takes more than a month for a juvenile hatched from a cocoon to become adult. The adult can produce 1 cocoon between 1.5 and 5.5 days and 1 cocoon can hatch into 4-5 juveniles between 14 and 28 days (Fayolle, 1982), depending on local abiotic conditions.

The data for cocoons were not as regular as for general worm abundance and biomass (Figs. 3 and 4). The average cocoon abundance during the whole experiment was 4.7, 4.7, 6.5, and 6.1 × 10⁶ individuals m⁻² for vermicompost 1-4, respectively. The highest mean number of cocoons produced per earthworm was 8.1 ± 2.8, and the overall mean value for the four vermicomposts was about 3.7 ± 1.2. Previous studies indicated from 1.9 to 2.9, in cattle and swine manure solids (Gunadi et al., 2003), or 6.8-12.4 cocoons/earthworm between the 3nd and 11th week of vermicomposting of solid textile mill sludge mixed with farm manure (Kausik and Garg, 2004). The values of cocoon numbers per earthworm in the present study were similar to those previous results, suggesting that the microclimate in the material was suitable for cocoon production, and the fecundity of the earthworms was not reduced.

There was no significant change in the four vermicomposts, except in v2 after 1 week and in v3 after 4 weeks. These results vary from cocoon numbers per earthworm in the present study were similar to those in the previous results, suggesting that the microclimate in the material was suitable for cocoon production, and the fecundity of the earthworms was not reduced.

In the present study, the biomass (wet weight) should continue to increase because new cohorts of juveniles will grow until the adult stage, while lifespans of up to 216 weeks have been observed for E. andrei in favorable conditions (Cluzeau, 1993). High earthworm densities would limit earthworm multiplication (Frederickson and Ross-Smith, 2003).

3.4. Effect of water reuse on pollutant concentrations

When the liquids passed the vermicompost, organic matter and minerals were retained by the vermicompost material. The observed decreases in the concentrations were roughly: dry matter, 40%; organic matter, 50%; NH₄-N, 60%; total nitrogen, 50%; total phosphorus, 30%; organic carbon, 50%; inorganic carbon, 60%. Potassium concentration was almost unchanged.

* Average of two values during the second week.

These reductions were smaller than in previous results (Bouché and Soto, 2004).

Despite the reuse of the wastewater and the collection of swine excreta, the concentration of pollutant in the water in the tank after vermicilfering at the end of the experiment remained lower than that of the liquid after sieving (Table 2).

Ammonia was removed from the liquid through rapid adsorption on organic matter after sprinkling, and progressive organization by the biomass. This removal of ammonia was no doubt the cause of the significant decrease (around 50%) in the ammonia emission from the building. The odor in the effluent was removed as it passed through the vermicilfer.

Compared to the customary output from water treatment systems, the concentrations in the recycled water were high, but they are acceptable for recycling the water inside the swine facility because odors and ammonia are strongly reduced, and because we observed no health impact during 4 years' trials. To improve the wastewater quality, a further treatment with macrophyte lagooning was added after the vermicilfer (Morand et al., 2005; Hamon et al., 2006). It was designed to increase not only nutrient reduction and biomass production (Gumbricht, 1993; Greenway, 2005; Bojarczuk and Tonderski, 2007), but also retention time (Tashiro et al., 2003; Kreuzinger et al., 2004), and to accumulate rainwater to compensate for the evaporation of the vermicilfer and the swine facility.

3.5. Mass balance shows further abatement between sprinkling events

The mass balance of the vermicilfer results from biological, physical and chemical reactions, including the adsorption of molecules and ions, oxidation-reduction of organic matter, the behavior of earthworms and their synergistic effects with microorganisms (Bouché and Soto, 2004).

The calculated mass balance of all the substances put into and taken out of the experimental system gives rise to a mass of matter which is greater than the input through sprinkling (Table 3).

The recovery of C, N, P, K ranged from 83 to 91%, which validates the integrated method to sample solids and liquids, as well as the methods to measure the gas emissions.

The volumes of material fell clearly in all four vermicilfers by 13–16% (Fig. 5). This is the result of active composting inside the vermicilfer.

The losses of C, N, and dry matter were far above the error level of 5%. The minimum inputs to the vermicilfer can be estimated as 2/5 of the mass found in the slurry (2 days sprinkling the vermicilfer, 5 days output to slurry tank 3). Therefore, they can be estimated at about 100, 60, 10, 3, 5 kg for dry matter, C, N, P, and K, respectively. With these values, the mass balance of P and K in the vermicilfer is within 5% of its theoretical value. It shows that the possible error, due to sampling and analyzing the solids, is acceptable for using this methodology on a farm scale.

3.6. Increased water, carbon, and nitrogen volatilization

The amount of water evaporated by the system was large in relation to the inputs (90% of the water added with the food). This can be related to the flushing system used and the vermicilfer. Most of the evaporation occurred in the swine facility. Compared to a conventional slatted-floor system, evaporation increased by around 50% of the water in excreta. Only 13% of the water added with the food was evaporated by the vermicilfer, corresponding to 30% of the water in excreta.

The mass of C lost from the vermicilfer can be estimated from the C measured in the solids and from the CO₂ measured in the air. This second estimate is around 100 kg (Table 4). It confirms that the loss is higher than the theoretical input, but it is half of that estimated from the solid analysis (around 200 kg). This difference can be explained by the experiment's short duration: the inputs and outputs of the pilot are close to the initial and final stocks in the swine facility and in the vermicilfer. The emissions from the vermicilfer are low compared to its initial and final stocks, so an error of 5% in the estimated initial and final stocks can induce a large error in the mass deficit.

The ammonia emission of the system was less than that of a standard slatted-floor breeding system. French swine facilities are thought to emit around 20% of excreted nitrogen as ammonia (CGEN, 2003). In the present pilot, the emission from the building was around 10% of excreted nitrogen, while emission from the vermicilfer was less than 1%. Even if a high error on the emission is assumed (cf. C emission), the ammonia emission of the vermicilfer is very low. The nitrous oxide emission from the vermicilfer was higher than its ammonia emission but it was also less than 1% of the excreted nitro-

Fig. 5 – Changes of volume of materials in four vermicilfers after 1, 2, or 4 weeks.
gen. This indicates that nitrification-denitrification occurred within the vermicomposter.

As nitrogen did not accumulate in the vermicomposter (Table 1), and ammonia and nitrous oxide emissions remained low, most of nitrogen loss was assumed to be as N₂ and thus not transferred into other polluting phases (solid or gas). This result also implies that the sprinkled quantity of liquid manure in this study did not compensate for the nitrogen consumed by the earthworms and the microorganisms. Therefore, an increase in the organic load to the vermicomposter is possible (between 1 and 2 m² vermicompost/finishing swine). The vermicomposter can be further used to recycle the water in the swine facility without pollution transfer.

3.7. Accumulation of P and K added with the diluted swine effluent

P and K accumulated in the vermicomposter by around 10-20%. This result was close to that of former studies involving P and using vermicompost to treat municipal wastewater (Aguilera, 2003; Bouche and Sohn, 2004). The vermicomposter can retain some P initially and thus decrease the P content of the effluent. When the P content in the vermicomposter increases, so does the release of P, and the filtering efficiency for P reaches equilibrium. For P and K, this experiment was too short to observe saturation. The vermicomposter material should be changed when the material is saturated, and the compost could be used as P and K fertilizer on the farm.

3.8. Design and management of vermicomposter for diluted swine manure

About 30% of the water, 25% of the C and 20% of the N from the excretion was lost as gases in the vermicomposter for the whole experimental period (Table 1). The vermicomposter removed about 85% of the C and 65% of the N in the swine excretion (related to 2 seventh of total excretion because of 2 days/week sprinkling). The losses would exceed the excretion with 0.4 swine m⁻² vermicomposter, based on 2 days' sprinkling per week with the sieved slurry. The C and N lost from the vermicomposter corresponded to 116 g C m⁻² and 8 g N m⁻². Without the sieve, the treatment capacity would be about 0.3 swine m⁻² on the basis of total C excreted, and about 0.25 swine m⁻², on the basis of total N excreted.

For practical use of vermicompost on swine farms, the sprinkling program and vermicomposter surface area should be adapted to maintain a moderate temperature and humidity in the vermicomposter material. Discontinuous sprinkling or omission of effluent sieving can be used to adjust to gaseous losses of C and N.

The design and management of the vermicomposter can influence the water evaporation. If the frequency of sprinkling increases, then the relative duration of the evaporation periods will decrease. Alternatively, if the area of the vermicomposer increases, the evaporation will increase. Increased evaporation reduces the cost of transporting the vermicompost.

The addition of wood chips contributed to the supply of C to the metabolism in the vermicomposter and to maintain the porosity for water circulation and gas diffusion. The wood chips should be added before the cold season to improve temperature conditions inside the vermicomposter.

The observation of dead or escaped earthworms is a simple bioindicator to manage the nutrient load of the system. Fewer worms will increase the risk of excessive organic input, which may lead to the death of worms by anaerobiosis in the vermicomposter. If the nutrient supply is lower than the needs of the population, or if humidity is too low, some worms will escape and the population will not increase, reducing the efficacy of the system.

4. Conclusion

Vermicompost can be used to treat diluted swine manure. The wastewater can be reused to flush the manure, inducing a reduction in ammonia emissions compared to rearing on a slatted floor with slurry accumulation. Vermicompost also resulted in higher volatilization of water, carbon, and nitrogen, reducing transportation costs.

An integrated methodology was developed to study vermicomposting in a swine facility. It can be applied on a farm. It deals with water treatment and gas emissions in order to avoid the possibility of pollution transfer through treatment. It shows that when recycling the water, the treatment capacity cannot be evaluated simply from the difference between input and output. The integrated mass balance should also be used because of the progressive accumulation or loss of matter in the water tanks and vermicomposter materials.

It was important to know the dynamics of the earthworm populations during the vermicomposting. These were not only related to the treatment capacity but also were a bioindicator of the experimental conditions and perhaps of pollutant input. The earthworm behavior and demographic parameters can be used as bioindicators to manage the nutrient input to the system and to maintain, for example, a low level of ammonia emissions.

Water is now an important factor in the management of swine manure, with frequent removal by flushing. In order to avoid excessive economic and ecological costs, the water excreted by the swine can be reused to flush the manure. The amount of water needed would decrease with continuous use of the vermicomposter, because much of it is evaporated either due to the flushing system design or due to biological activity heating the vermicomposter. Reuse of the water can include the construction of a water treatment plant using macrophytes for further nutrient exportation. The collected solids from the sieve and the vermicomposter can be used as organic fertilizer or recomposed. Other outputs from another extensive treatment plant, like macrophyte lagoon, could bring added value to the system.

A longer experiment is needed to assess the limitations of the system before using it on a commercial farm.
